

NPLCC FINAL PROGRESS REPORT

1. ADMINISTRATIVE INFORMATION

Project Title:

Implementing climate-smart resource management across multiple ownerships in southwestern Oregon

Agreement Number: PNW 14-IA-11261987-099

Project Period: January 2015-December 2016

Report Submitted: April 2017

Principal Investigator: David L. Peterson

Lead Agency: U.S. Forest Service

Address: U.S. Forest Service, Pacific Northwest Research Station, 400 N. 34th St., Suite 201, Seattle, WA 98103

Telephone: (206) 732-7812

Email: peterson@fs.fed.us

Cooperators:

Jessica Halofsky, University of Washington, Co-Principal Investigator

Gwyneth Myer, Southern Oregon Forest Restoration Collaborative, Co-Principal Investigator

Kerry Metlen, The Nature Conservancy, Coordinator for all aspects of the project including communication

2. PUBLIC SUMMARY:

Climate change will likely have significant effects on forest ecosystems worldwide. In dry Mediterranean regions, such as that in southwestern Oregon, USA, changes will likely be driven mainly by wildfire and drought. To minimize the negative effects of climate change, resource managers require tools and information to assess climate change vulnerabilities and to develop and implement adaptation actions. We developed an approach to facilitate development and implementation of climate change adaptation options in forest management. This approach, applied in a southwestern Oregon study region, involved establishment of a science–manager partnership, a science-based assessment of forest and woodland vulnerabilities to climate change, climate change education in multiple formats, hands-on development of adaptation options, and application of tools to incorporate climate change in planned projects. Through this approach, we improved local manager understanding of the potential effects of climate change in southwestern Oregon, and enabled evaluation of proposed management activities in the context of climatic stressors. Engaging managers throughout the project increased ownership of the process and outcomes, as well as the applicability of the adaptation options to on-the-ground actions. Science–management partnerships can effectively incorporate evolving science, regardless of the socio-political environment, and facilitate timely progress in adaptation to climate change.

3. EXECUTIVE SUMMARY:

The objective of this project was to build on previous climate change-related efforts in the Rogue Basin of southwestern Oregon to promote climate-smart strategic planning and project implementation. Specifically, our objectives were to: (1) implement recommendations from the *Rogue Basin Action Plan for Resilient Watersheds and Forests in a Changing Climate* in resource management and planning; (2) link key vulnerabilities with specific adaptation strategies and tactics on the ground; and (3) link adaptation with restoration, planning, and resource monitoring programs across multiple land ownerships. To achieve our objectives, we used an approach that relied heavily on participation of local specialists across multiple organizations to establish a science–manager partnership, develop climate change education in multiple formats, facilitate hands-on development of adaptation options, and convene a hands-on application of tools to incorporate climate change in planned projects and prioritize future projects under a changing climate. Through our science-management partnership, we built on the *Rogue Basin Action Plan* and conducted a climate change vulnerability assessment for forest and woodland resources in the Rogue Basin. We communicated information from the vulnerability assessment in a series of webinars and in a workshop. Vulnerability assessment information set the stage for hands-on development of climate-smart project activities for the Applegate Adaptive Management area, a joint Forest Service and Bureau of Land Management project area, in a workshop format. We also conducted a post-workshop field trip to illustrate the implementation of climate change information in on-the-ground management activities. By bringing together diverse local participants in a science–management partnership and presenting information on climate change vulnerabilities in the region in a range of formats, we improved understanding of the potential effects of climate change in the Rogue Basin, and enabled evaluation of proposed federal management activities in the context of climatic stressors. By engaging local managers throughout the project, we increased ownership of the process and outcomes, as well as the applicability of the adaptation options to on-the-ground actions. As has been shown in this case in southwestern Oregon, and in several other locations in the United States, science–management–public partnerships can effectively incorporate evolving science and enable timely progress in adaptation to climate change.

4. PURPOSE AND OBJECTIVES:

Climate change poses significant challenges to the sustainable management of forest ecosystems in the United States. With warming temperatures over the last few decades, changes in physical and ecological processes are already becoming apparent. For example, there have been declines in snowfall in many parts of the country. In the western U.S., there have been declines in snowpack, mountain precipitation, and streamflows. Drought severity has increased in several regions. The area affected by disturbances, such as insect outbreaks and wildfire, has also increased. These trends of increasing temperatures, changing precipitation patterns, and increasing extreme events such as drought and fire are expected to continue in this century, driving changes in forest ecosystems.

Adapting to climate change, or “the process of adjustment to actual or expected climate and its effects”, is critical to minimize the risks associated with climate change impacts. Significant progress has been made in climate change adaptation in the U.S. in recent years, in multiple sectors, levels of government, and in the private sector. At the federal level, adaptation planning has been spurred by President Obama’s Executive Order 13514, which requires federal agencies to evaluate climate change risks and vulnerabilities and develop climate adaptation plans, and by Executive Order 13653, which requires federal agencies to complete an inventory and assessment of (proposed or completed) changes in their policies, programs, and regulations that would help make ecosystems and the people that depend on them more resilient to climate change.

Along with increasing recognition of the importance of addressing climate change, these Executive-level orders have spurred increased climate change activity in federal natural resource management agencies over the last few years. This activity has led to a variety of assessments, strategies, guiding documents, and new agency positions and organizations focused on climate change. Currently, most federal agencies have broad-scale strategic plans that describe approaches and priorities for climate change in general, and for adaptation in particular, and several departments and agencies have built on initial strategic documents to increase capacity and develop more detailed plans for assessing vulnerabilities and adapting management to climate change. Much of the progress in climate change adaptation in natural resource management to date has been accomplished through collaboration between scientists and resource managers.

Although nearly all federal natural resource management agencies have an overarching response strategy for adaptation, and in some cases a framework for doing so, accountability for developing and implementing adaptation options has been minimal among federal agencies. Field units are rarely required to assess the vulnerability of resources to climate change or develop and implement adaptation responses. Many land managers would like to develop vulnerability assessments and adaptation plans at the field-unit scale, but in the absence of a mandate, sufficient budgets, and accountability for implementation, progress has been impeded.

We developed an approach to facilitate development and implementation of climate change adaptation options in forest management in the Rogue Basin of Southwestern Oregon (Figure 1). Home to many endemic plant species, the Rogue Basin has the highest vegetative diversity in the NPLCC. The Rogue Basin includes portions of the Klamath-Siskiyou Ecoregion, one of seven International Union for Conservation of Nature areas of global botanical significance in North America, and has been proposed as a World Heritage Site. Southwestern Oregon is also the warmest region of the NPLCC and has the most species to lose in a warmer climate. The pervasive nature of climate change, expected changes in ecological disturbance, and need for habitat connectivity dictate that conservation of biodiversity in this region use an all-lands approach to maintain ecosystem resilience over large spatial and temporal scales. Adaptation, restoration, and conservation in this climatically-sensitive region must proceed in the context of a long legacy of forest harvest, fire suppression, and environmental conflict about land use.

Prior to this project, multiple agencies and organizations in southwestern Oregon had made significant progress in collaborative restoration of forest landscapes and in projecting

project are also participating in SWOAP, including representatives from the Rogue-River Siskiyou National Forest, the Bureau of Land Management (BLM; Medford and Roseburg districts), and The Nature Conservancy.

5. METHODS, ORGANIZATION AND APPROACH:

Development of a Science–Manager Partnership

The first step in our process was to develop a partnership among scientists and local natural resource managers and specialists. We chose to build on a project led by the Southern Oregon Forest Restoration Collaborative (SOFRC) that resulted in a climate change action plan for watersheds and forests in the Rogue River Basin in southwestern Oregon. The SOFRC work provided a preexisting science–management partnership, which included U.S. Forest Service and BLM line officers, planners, and resource specialists, scientists from The Nature Conservancy, and others. We initially convened representatives from each agency/organization on conference calls to establish project scope, focal resources, timeline, and communication plan. These calls continued on a monthly to bi-monthly basis as the project developed, with substantial engagement from the local partners. A broader and more diverse group of participants was selected to participate in the webinars and workshop (see below).

Vulnerability Assessment of Forest Resources to Climate Change

The next step in the process was to gather existing information to assess the vulnerability of forest resources in the Rogue Basin to climate change. Vulnerability assessments address “the propensity or predisposition [of a system] to be adversely affected”, and are necessary to inform adaptation planning and reduce the negative consequences of climate change. The assessment considered the sensitivity (susceptibility to harm) and adaptive capacity (capacity to cope and adapt) for forest vegetation in the Rogue Basin. We also assessed potential exposure to climate change, a component of risk.

To assess potential sensitivity of vegetation, we built on the SOFRC plan and considered relevant paleoecological studies of climate and species distribution, as well as studies reporting trends in tree growth and species composition with recent climate change. Available vegetation and fire model projections, including those from empirical and process-based models, were also considered. More than simple literature reviews, the sensitivity assessments involved evaluation of the quality and relevance of the science for the vegetation types of the region. To assess potential adaptive capacity of ecosystems in southwestern Oregon, we also utilized spatial information to identify landscape locations likely to be resilient to climatic changes, based on geophysical diversity and landscape permeability to migration. To assess exposure, we used global climate model projections in the U.S. National Climate Assessment.

Communication of Climate Change Information

To communicate information from the climate change vulnerability assessment, we developed and delivered an engagement strategy for local managers that included a series of five webinars. The webinars provided an overview of climate change impacts to the Rogue Basin and then delved into topics of interest to local resource managers: potential effects of climate

change on hydrology, aquatic organisms, forest and vegetation, and terrestrial wildlife. These webinars built up to a one-day hands-on workshop and a field trip to facilitate applied adaptation planning. We provided information on an assessment of adaptive capacity of ecosystems in the region and its incorporation in a framework for prioritizing restoration work in southwestern Oregon under changing climate (Rogue Basin Cohesive Forest Restoration Strategy: A Collaborative Vision for Resilient Landscapes and Fire Adapted Communities; <http://sofrc.org/2015/08/the-rogue-basin-cohesive-forest-restoration-strategy/>).

Hands-On Development of Adaptation Options

The webinars provided a base of information that we reviewed in the first half of a one-day workshop, allowing ample opportunity for questions, open discussion, and feedback on the vulnerability assessment. The workshop was attended by over 40 participants, comprised of approximately 50% Forest Service, 40% BLM, and 10% university and other organizations. The second portion of the workshop was used to develop adaptation options in small working groups. This exercise focused on a planned project and modifications or additional activities that could be added with an explicit climate change consideration. We chose this approach to illustrate how climate change information can be applied to on-the-ground management actions and to facilitate implementation of climate-informed practices in the region. This approach built on a process honed in previous climate change adaptation workshops conducted across the western U.S. over the last decade.

The project that was evaluated in the workshop is located in the Applegate Adaptive Management Area (AMA) (Figure 1), a joint Forest Service and BLM-managed watershed, focused on the Upper Applegate planning area. A federal project team had developed goals, objectives, and general project activities prior to the workshop. Team members from the project team were present to answer questions and provide information about the project and project area. We used a modified version of the Climate Project Screening Tool, originally developed by Forest Service staff for a similar purpose, to aid participants in evaluating project activity outcomes under a changing climate. Each small (3–10 person) working group answered the following questions about project goals and proposed activities and reported on the outcomes:

1. Are there any challenges to meeting the goals/objectives because of climate change?
2. How may the project activity need to be revised when considering impacts from climate change (e.g., consider spatial scale, temporal scale, features)?
3. How do the new or revised approaches compare in effectiveness and feasibility to the proposed activity and accompanying goals?

Field Trip Illustrating Climate-Informed Management Actions

To further illustrate how an on-the-ground project could incorporate climate change, the workshop was followed by a half-day field trip to the Table Rocks oak restoration project area (Figure 1). This joint project included several agencies and non-governmental organizations working to reintroduce characteristic fire to increase future resistance and resilience of oak woodlands. The field trip leaders gave an overview of the process and planning behind the Table Rocks project. Local scientists described how climate change was considered in the project using future white oak habitat projections and a forest restoration prioritization

framework developed for the region, which focused on promoting landscape resilience, mitigating wildfire risk, protecting and promoting complex forest in sustainable landscape settings, and concentrating conservation efforts on climate resilient landscape facets. This information provided a climate adaptation framework for planning. Building on this framework, non-governmental organization and agency collaborators successfully attained funding from government and non-governmental sources for actions on agency and private land, and they are currently implementing treatments, with multiparty monitoring driving adaptive management.

6. PROJECT RESULTS:

Potential Climate Change Effects on Forest Ecosystems in the Rogue Basin

In the Rogue Basin, increased annual temperatures and seasonal precipitation shifts will likely result in increased summer moisture stress for forest and woodland ecosystems. Average annual temperatures in the region are likely to rise by approximately 1.8 °C to 5.4 °C by the end of the century, and summer precipitation may decrease by as much as 30% by the end of the century. Summer water deficit and drought severity will likely increase because of increased temperatures and lower precipitation in summer. Reduced snowpack and earlier peak stream flows, along with the potential for more extreme precipitation events, will increase flood risk in winter and early spring, and result in lower summer stream flows. Wildfire risk will also increase with increasing temperatures and earlier snowmelt.

The diverse biota of the serpentine soils of the Siskiyou Mountains have been stable over millennia, even as other vegetation types have shifted. However, rapidly changing climate and land management effects have been correlated with significant shifts in the herbaceous communities of the Siskiyou from 1950 to 2008, suggesting that species with narrow ecological amplitude may be at risk. Documented compositional changes reflect adaptation to a warmer climate, with reduced cover of species with northerly biogeographic origin, reduction in specific leaf area, and an increasing proportion of the community comprised of dry habitat species.

Modeling projections for future vegetation communities suggest that grasslands, chaparral, and montane forests are likely to expand, while alpine and subalpine forest cover is expected to contract under climate change (Table 1). The process-based MC1 model suggests that coastal coniferous forests of the Rogue Basin may transition to more hardwood-dominated subtropical forests with decreases in frost, and that montane coniferous forests could transition to more xeric evergreen forest and oak woodland. Oak woodlands and prairie ecosystems of the Pacific Northwest may be well-suited to future climate, although they will likely be affected indirectly by other factors, such as high-severity fire and invasive species. Tree growth will likely decrease for many species with increasing summer drought stress. Drought stress can increase host tree vulnerability to insects and disease, and combined with elevated temperatures, may drive tree mortality.

Climate change is projected to increase the likelihood of wildfire, fire severity on conifers, and suppression difficulty across western North America. Severe fires release more carbon than fires of lower intensity, and can turn forests into net carbon sources for years to decades, although this is not always the case. In the Mediterranean forests and woodlands of the Rogue Basin, the likelihood of very large fire is expected to increase, possibly by 300%–

500% by 2070, shifting the conversation from if fires will burn to how they will burn. Increased incidence of large, severe fires will likely affect ability of forest ecosystems to provide ecosystem services, including carbon storage, water quality, wildlife habitat, and recreation opportunities.

Large, high severity patches can fail to regenerate with conifers because of long distances to seed sources, harsh environmental conditions, and competition from other vegetation. Lack of regeneration can be exacerbated by future fires, where severe fire patches have been shown to promulgate severe fire patches in subsequent fires, effectively reinforcing the tendency to move from forest to shrub or grassland. Long-term conversion of forest to other vegetation types can compromise sequestration of carbon and alter wildlife habitat attributes, exacerbating climate change impacts described above.

Table 1. Summary of vulnerability of vegetation types in the Rogue Basin in southwestern Oregon, as determined by the climate change vulnerability assessment described above. Vegetation types with high vulnerability to climate change are likely to contract significantly or may experience extensive mortality in the future, whereas vegetation types with low vulnerability to climate change are likely to maintain current area or increase in area (although their distribution across the landscape may shift). Composition of all vegetation types is likely to shift to more drought and fire tolerant species. Late-successional forest structures, such as snags and down wood, will be vulnerable to fire.

Vegetation Type	Potential Climate Change Impacts	Vulnerability to Climate Change
Alpine vegetation	More precipitation falling as rain rather than snow; earlier snowmelt; lower snowpacks; longer growing seasons; contraction of climatically-suitable habitat for alpine vegetation	High
Subalpine forests	More precipitation falling as rain rather than snow; earlier snowmelt; lower snowpacks; longer growing seasons; possible increases in fire and drought; contraction of climatically-suitable habitat for subalpine vegetation	High
Montane forests	Lower snowpacks; longer growing seasons; increased area burned and burn severity; increased summer water stress and drought severity; shifts to more xeric evergreen forest and oak woodland vegetation	Moderate
Dry forests	Increased area burned and burn severity; increased summer water stress and drought severity; potential for increased post-disturbance regeneration failures; shifts to more xeric evergreen forest and oak woodland vegetation	High
Oak woodlands	Increased area burned and burn severity; increased summer water stress and drought severity, invasive non-native annual grasses	Moderate
Chaparral	Increased area burned; increased summer water stress and drought severity	Low
Grasslands	Increased area burned; increased summer water stress and drought severity, invasive non-native annual grasses	Low

Adaptation Options for the Applegate Adaptive Management Area

In a drought-prone and fire-prone region such as southwestern Oregon, reducing stand density and reintroducing characteristic low and mixed severity fire are primary actions for increasing forest resilience to climate change. Reducing stand density with thinning can increase water availability and tree growth and vigor by reducing competition. Decreases in forest stand density, coupled with hazardous fuels treatment, can also increase forest resilience to wildfire. Managers at our adaptation workshop suggested increasing the amount of thinning planned in the Applegate AMA, and they also suggested altering thinning prescriptions and placement (Table 2). For example, forest thinning prescriptions may need to further reduce forest density and increase gap sizes to provide for establishment and growing conditions for desired drought and fire tolerant tree, shrub, and herbaceous species. Thinning treatments could also be prioritized in locations where climate change effects, particularly increased summer drought, are expected to be most pronounced, in high-value habitats (e.g., riparian zones) and in high-risk locations such as the wildland-urban interface (Table 2). Managers also suggested that prescribed burning be used more frequently to mimic effects of wildfire in reducing stand density and fuels, thus increasing the likelihood of favorable outcomes when subsequent wildfires occur.

Increasing fire will put forest legacy structures, such as large, old trees, snags and downed wood, at risk. Legacy structures have disproportionate habitat value for a large number of species. Managers in southwestern Oregon suggested that legacy structures be protected from fire by thinning around them and reducing duff build-up at the base of legacy trees (Table 2). To improve wildlife habitat, thinned and fire-killed trees can be left as structure rather than being removed. Increasing the density of legacy structures may be particularly effective in younger forests near late-successional forest to increase habitat quality and connectivity.

Many plant species will be subjected to increasing stress in a changing climate, and some species and genotypes may be unable to adapt to rapid warming. Similarly, areas with low species and genetic diversity will likely be more susceptible to the stressors associated with climate change. Genetic stock that is better adapted to climatic conditions of the future will be more resilient and increase overall ecosystem resilience. Thus, managers suggested planting species and genotypes that will be better adapted to future conditions (Table 2). Promoting species and genetic diversity, through plantings and in thinning treatments, will likely increase forest resilience to changing climate. Promoting landscape heterogeneity in terms of diverse species and stand structures across a landscape mosaic may also help to decrease size and severity of wildfire, and insect and disease outbreaks.

Reducing the effects of existing non-climatic stressors on ecosystems, such as landscape fragmentation and invasive species, will likely increase ecosystem resilience to climatic changes. Early detection, rapid response was suggested to prevent invasive species establishment. In particular, treatment of species that have the potential to delay development of desired vegetation structure can be prioritized.

There are significant uncertainties associated with future conditions under changing climate, and managers in southwestern Oregon recognized the critical role that learning through experimentation and monitoring will play in coping with future uncertainty. They suggested experimentation with thinning prescriptions, and potentially conducting treatments in locations such as riparian areas where thinning is not permitted under current policy.

Monitoring will also be critical in detecting changes in plant species regeneration, growth, and mortality with changing climate and to determine treatment effectiveness under climate change. For example, tracking tree species regeneration and distribution will help managers determine how species are responding to climatic changes and how to adjust management accordingly (e.g., guidelines for planting). Managers did not suggest any revision to underlying goals and objectives, though it should be acknowledged that the goals and objectives were general and mainly focused on restoring habitat structure and function, and thus consistent with goals to increase resilience to climate change.

Table 2. Revisions to the Applegate Adaptive Management Area restoration project activities, suggested by managers after considering climate change.

Project objectives	Project activity	Challenges to meeting goals/objectives because of climate change	Suggested revision to project activity	Potential effectiveness and feasibility of the revised activity
Restore plantations to more resilient conditions	Non-commercial thinning	Plantation stock may not be well-adapted to future climate, and there may be decreased resistance to certain insects and disease.	Create gaps, and reduce planting density to reduce moisture stress; plant diverse genotypes and species that may be better adapted to future conditions; use fire instead of mechanical thinning when possible to reduce future fire risk.	Revised treatments may be more expensive, but they will likely decrease risk of fire and insect and disease outbreaks.
	Commercial thinning	Increased moisture stress and fire risk.	Target plantations that might threaten more resilient areas; use radial/donut thinning around pines; assess past management practices to determine priorities for treatment.	Without long-term maintenance, there is uncertainty about whether thinning treatments will be useful over the long term.
Reduce risk to communities and other developed areas from uncharacteristic wildland fire	Non-commercial thinning	Increased fire risk.	Increase thinning activities in the wildland-urban interface.	Budget is extremely limited and treatments need to be maintained to be remain effective.
Mitigate natural stand conditions that contribute to insect and disease outbreaks	Commercial and non-commercial thinning	Increased insect and disease outbreaks, particularly in overstocked stands.	Increase thinning and prescribed fire activities; target older, mid- to closed-canopy stands; target pine-oak woodlands and remove shade tolerant species.	It is difficult to treat a sufficient area to have an impact at the landscape scale; windows for prescribed burning are small, and tolerance for smoke is low.
Develop and maintain	Strategic placement of	Increased fire risk and vegetation	Develop habitat where it is resistant to the effects of	

complex forest habitats for wildlife	habitat development treatments	type shifts.	climate change (e.g., oak woodlands will likely be more resistant than Douglas-fir stands); create redundancies in habitat across the landscape; create habitat connectivity.	
	Legacy tree retention	Increased fire risk with climate change, and increased risk of loss of legacy structures.	Favor certain species depending on aspect (e.g., more drought-tolerant pine or oak on warmer south-facing slopes); select higher vigor trees for retention; thin around legacy trees and remove duff from around the base.	Revisions will require more time in selecting trees for retention, and they will increase costs; designing logging systems will be more complicated.
Treat non-native plants	Increase resistance to non-native plant invasion	Vegetation shifts and potential for disturbance to increase risk of invasion.	Seed native species and use locally-sourced seed; reduce impacts of treatments on existing native species; use early detection/rapid response for non-natives.	May need to develop new treatments for non-natives (e.g., different herbicides); monitoring will need to be increased.
Maintain watershed health (water quality, fish habitat, and site productivity)	Increase forest canopy cover	Increased fire risk in riparian areas with less summer precipitation and lower summer stream flows.	Allow thinning in riparian areas to increase tree size and function.	Need to design thinning treatments that have "no effect" for water quality and water temperature.
	Planting native vegetation	Increased summer drought stress and risk of mortality in planted vegetation.	Increase diversity of shrubs and trees to provide functions (shade, water storage) that may help create climate resilience in riparian areas	

7. FINDINGS AND CONCLUSIONS:

Similar to trends identified for the greater western United States, climate change will affect forests of the Rogue Basin in a number of ways, but fire and drought will likely be the key agents of change. Fire suppression and land management have resulted in increased forest density and risk of high-severity wildfire. A recent study estimated that 1.0 to 1.7 million forested hectares (57%) in southwestern Oregon are in need of thinning or prescribed fire to move towards natural range of variability in forest structure. Increased drought with climate change will likely stress high-density forests, increasing their vulnerability to insects and disease, and exacerbating risks of high severity fire. Interactions among these multiple stressors may result in rapid change in forest ecosystem composition and structure, and the ecosystem services provided.

Decreasing forest density through thinning and prescribed fire can both reduce the risk of high-severity fire, and mitigate the effects of drought. Using thinning and prescribed fire to

reduce risk of high-severity fire was a clear focus of adaptation actions developed by resource managers in our workshop, as it has been in other similar efforts. While it may be feasible to reduce effects of drought and fire at the stand or project level, and treatments can be prioritized in climate change refugia and/or the most vulnerable portions of the landscape, the spatial scale of treatments would need to be increased considerably, and maintained over time, to function effectively at a large spatial scale. Increasing the scale of treatments would require increased budgets. It would also require increasing public acceptance of active management, including use of prescribed fire, which may come with increased understanding of the connections between ecological and social dynamics, and addressing the concerns of fire-prone communities regarding management of federal lands. In the case of the Rogue Basin, strong social networks and collaborative groups, such as SOFRC, formed of public, scientists, and managers, help foster communication, engagement, and crucial momentum for forest restoration and climate adaptation.

Carbon sequestration and wildlife habitat are also important considerations in determining the scale and placement of treatments. Carbon emissions from mechanical treatments and prescribed fire are significant, but these treatments can reduce subsequent fire severity, potentially reducing impacts on soil and wildlife habitat, and reducing carbon emissions in subsequent wildfires. There are uncertainties associated with the long-term effects of thinning and fuel treatment regimes on carbon storage in a changing climate, and further research is needed to evaluate potential short-term and long-term costs and benefits. Managers will have to consider multiple values, ecosystem services, and ecosystem stressors (e.g., fire, insects and disease, and invasive species) in determining treatment type, scale, and intensity with climate change.

Maintaining the status quo is often prevalent in a decision-making environment characterized by uncertainty. Reduced scientific certainty about effective climate change adaptation options, and consistent policy about climate change adaptation will improve, but not ensure, implementation of vulnerability assessments and adaptation plans. Increasing the knowledge base on climate change effects and tools for implementing adaptation actions on the ground will strengthen confidence about taking actions that may depart from a previous course of action. Our approach involving education, tools, and facilitated process to develop adaptation options for specific projects, can provide confidence for making adaptive shifts in management under a changing climate; particularly when supported by a strong collaborative dynamic.

8. LESSONS LEARNED AND RECOMMENDATIONS:

By bringing together diverse local participants in a science–management partnership and presenting information on climate change vulnerabilities in the region in a range of formats, we improved understanding of the potential effects of climate change in the Rogue Basin, and enabled evaluation of proposed federal management activities in the context of climatic stressors. Multiple educational tools were utilized, including webinars, a workshop, and a field trip, allowing us to reach more individuals (over 200 in all). But the learning process was not unidirectional; in addition to managers learning about climate science and potential impacts, scientists learned about local effects, management context and constraints, and application of

science to a specific project, thereby propagating adaptation through a co-production of knowledge. The Climate Project Screening Tool was effective in facilitating the shared learning process. Finally, by engaging local managers throughout the project, we increased ownership of the process and outcomes, as well as the applicability of the adaptation options to on-the-ground actions.

The Applegate AMA project team members intend to use the information from the workshop to help inform the development of project activities. Not including private landowners and a broader stakeholder group was a limitation of our approach, and a next step will be to include private landowners, local organizations, and the public to further develop a collaborative proposal for management actions in the AMA, account for the potential effects of project activities on ecosystem services, and develop support for project activities. Many of the proposed changes in vegetation management developed by resource managers in the workshop will provide opportunities to implement adaptive management, where feedback from monitoring provides direction for future management. Monitoring the effectiveness of treatments in the Applegate AMA and similar projects will be critical to refine effective adaptation strategies and improve ongoing planning at regional scales.

In some ways, climate change adaptation in vegetation management is a long-term management experiment. Given that there is no direct historical analog for many of the conditions and circumstances that forest managers have encountered and will continue to discover, uncertainties will continue to exist, even as our knowledge base evolves. Socioeconomic and ecological effects of changing climates will become more evident, but vulnerability assessments and timely implementation of adaptation plans will increasingly be essential to ensuring sustainable management of forests for a range of economic goods and ecosystem services. As has been shown in this case in southwestern Oregon, and in several other locations in the western United States, science–management–public partnerships can effectively incorporate evolving science and enable timely progress in adaptation to climate change.

9. MANAGEMENT APPLICATIONS AND PRODUCTS:

As a part of this project, we worked with decision-makers for the Table Rocks Oak Climate Adaptation Project to ensure implementation of “climate-smart” actions. We expect that the adaptation ideas developed in the workshop for the Applegate AMA will directly influence on-the-ground activities in the project area. The Rogue Basin Cohesive Forest Restoration Strategy (<http://sofrc.org/2015/08/the-rogue-basin-cohesive-forest-restoration-strategy/>) will likely be used for prioritizing future restoration activity in the Rogue Basin. But perhaps most importantly, the webinars, workshops, field trip, and other interactions we had with land managers in the region helped to increase their understanding of potential climate change effects and increase their capacity to respond to those effects. Though difficult to measure, the knowledge base established through project activities will help ensure that climate change is incorporated into future land management decisions, including those related to projects, planning, monitoring. This project also helped to further establish partnerships among multiple agencies and organizations, setting the stage for a larger, regional-scale climate change vulnerability assessment and adaptation effort (<http://adaptationpartners.org/swoap/>).

Project Cooperators:

Donald Boucher (Rogue River-Siskiyou National Forest) – Applegate AMA project coordinator; helped to guide workshop activities to make them applicable to the Applegate AMA project.

Louisa Evers (Bureau of Land Management) - Leadership team member who helped to plan webinars, workshop and field trip; coordinator for activities on Bureau of Land Management lands

Terry Fairbanks (Bureau of Land Management) - Leadership team member who helped to plan webinars, workshop and field trip

Anthony Kerwin (Bureau of Land Management) - Leadership team member who helped to plan webinars, workshop and field trip

Ken Wearstler (Rogue River-Siskiyou National Forest) - Leadership team member who helped to plan webinars, workshop and field trip; coordinator for activities on Forest Service lands

Project Deliverables:

- Project website: <http://sofrc.org/2015/09/implementing-climate-smart-resource-management-across-multiple-ownerships-in-southwestern-oregon/>
- Geodatabase for restoration prioritization, containing data used in the Rogue Basin Cohesive Forest Restoration Strategy
- Series of (five) recorded webinars describing potential effects of climate change in the Rogue Basin and related tools (190 total webinar views)
- Science-management workshop to increase understanding of potential climate change impacts, and to develop adaptation strategies and tactics specific to the joint Forest Service and BLM Applegate AMA (43 workshop participants)
- Field trip to illustrate the incorporation of climate change information in on-the-ground management activities (18 field trip participants)
- Peer-reviewed publication describing the project and its outcomes (Halofsky et al. 2016; see below)

Study results will be communicated to the management and policy communities through the peer-reviewed publication and through presentations for resource managers and stakeholders (see outreach section below). We also look forward to participating in an NPLCC webinar.

10. PUBLICATIONS AND OUTREACH:

Project outreach activities included:

- Webinar series (recorded and available on the project website) describing the climate change vulnerability assessment and related tools for the Rogue Basin
- Peer-reviewed publication describing the project and its outcomes (Halofsky, J.E., D.L. Peterson, K.L. Metlen, M.G. Myer, and V.A. Sample. 2016. Developing and implementing climate change adaptation options in forest ecosystems: a case study in southwestern Oregon, USA. *Forests* 7: 268. doi:10.3390/f7110268)
- Presentation on the project by K. Metlen to the Fish and Wildlife Service in southwest Oregon
- Project webinar for the NPLCC (*expected*)

11. Signature: The Agreement Project Manager should sign and date the final report to certify their submittal of the report.
